# RADIOLOGICAL ANALYSIS OF BIOLOGICAL SAMPLES COLLECTED 

 AT ENIWETOK MAY 16, 1948Lauren R. Donaldson
Allyn H. Seymour John R. Donaldson

Applied Fisheries Laboratory University of Washington Seattle, Washington

Radiological Analysis of Biological Samples Collectod At Enimetok May 16, 1948.*
by
Lauren R. Donaldson, Allyn il. Seymour and John R. Donaldson Applied Fisheries Laboratory
University of Fashineton, jeattle

## Introduction

On llay 16, 1945, the day following the Runit Island test, a collection of marine organisms was made from the reef area about one and ono-fourth miles north of the test site. This collection was used as a point of reference for the contamination studies planned for later in the season.

Arrangements for the expedition to make the collection were handied by Captain James S. Russell, U.S.N., Test Director, and Colonel James P. Cooney, M.C.

The collection was made by Dr. Lauren R. Donaldson assisted by Dr. David B. Langmir, Dr. Paul Aebersold, lir. James Pickard, Commander Christian Engleman, U.S.I.. With Captain Mallory as radiation monitor.

## Collecting Area

The collecting area was chosen some distance (one and one-fourth miles) from the target area so as to be outside of the area of greatest fall-out but still within the general fall-out pattern. Samples of aquatic life were obtained from the waters on both sides of the exposed reef. At low tide the material collected was in water 2 to 4 feet deep.

* This report is based on work performed under Contract No.il-28-094meng-33 with the Atomic Energy Comission.

## Collecting Methods

Samples were collected from areas surrounding isolated coral heads. After selecting a coral head with a variety of forms about it a small quantity of powdered derris root, 2 to 3 pounds of 5\% rotonone, was worked into the water. At the warm temperatures that prevailed fishes were immobilized and died in a few mimtes. Attached and sedentary forms were collected in the vicinity of the same coral head to complete the sample.

The material collected was first preserved in $4 \%$ formalin, then transferred to $70 \%$ alcohol for shipment to the Applied Fisheries Laboratory for ashing and counting. Some surface activity was undoubtediy lost by this method of handlinge

## Proparation of Material for Counting

To reduce the material to a convenient form for counting, small samples, usuaily about one gram in weicht were placed on one inch stainless steel plates and reduced to an ash. The samples were heated to $120^{\circ} \mathrm{C}$. on a hot plate to start the reduction. After beating sufficiently to char, a drop of olive oil was added to reduce sputtering and give better distribution of the material on the plate. The trays with the tissue residue were then placed in a muffle fumace and the temperature
 to $500^{\circ} \mathrm{C}$. and maintained until a mite ash was obtained. A drop of nitric acid was then added and the samples get aside to cool. After cooling the plates were mounted on cards and covered with cellophane for counting.

## Countins : Ie thod:

The beta-samma activity was determined by counting in a Victoreen unit, the scaler being lodel X-327, at the Applied FIshories Laboratory, University of \%ashincton. Counting was started as soon as material could be returned fron the test site, processed and ashed. The first counts were made on :ay 22, 1948, while other trays were not counted until September 1, 1948.

Some of the counts of activity exceeded the capacity of the scaler. There such high counts were obtained the amount of material on a plate was reduced or the material set aside to decay before counting. Fron decay curves the earlier count could be calculated.

The samples were corrected for background, for weiflit of samples and for geometry. The background counts averaged 17.0 per mimute. Using a U. S. Bureau of Standards Ra D + E standard of approximately 108 disintegrations per second the geometry of the unit was calculated as being 18.0 per cent. No correction was made for scattering, for self-absorption, for absorption by air, and by counter window or for the probability of ionization.

## Calculation of Counts

The activity counts obtained were converted to millimicrocuries per kilogram of sample and recorded in Table I. So convert counts per minute per gram, to millimicrocuries per kilogram the following formula was used:

$$
\mathrm{m} / \mathrm{uc} / \mathrm{k}_{\mathrm{S}}=\frac{\text { net count per mimuto }}{(\text { sample wt. })(\text { jeometry })(2.2)}
$$

 Collection Expressoc as millimicrocurios per Kilogran of tret Tissue and Arrmgod as to Jath Counted.

* above capacity of scaler

If the number of dis_integrations per second for one curie is $3.7 \times 10^{10}$ and this value is corrected for conversion to minutes and then the equation above is converted to milifmicrocuries the resulting value is the 2.2 that appears in the denominator of the equation.

The per cent error in counting was insignificant because of the relatively high rate of disintegration.

## Discussion of Resurits

The data recorded in rable I indicates an appreciable uptake of active material by aquatic forms collected about one and one-fourth miles north of Runit Island on the day following the test.

The fish material ashed and counted during late May, based on seven specimens, had the greatest concentration of active materials In the gut, where an average of 51,800 millimicrocuries per kilogram of material was found. The counts in the liver of $3810 \mathrm{~m} \mu \mathrm{c} / \mathrm{kg}$ indicate that absorption is taiding place. Surface contamination with the material possibly adhering to the mucous cover of the body is indicated by the $2150 \mathrm{~m} / \mathrm{ac} / \mathrm{kg}$ found as an average count in the skin. The gills ( $1670 \mathrm{~m} / \mu \mathrm{c} / \mathrm{kg}$ ), the bone (1540) and the mascle (201) had decreasing amounts of activity.

Fish material ashed and counted during mid-תune, late dugust and early September had counts with about the same distribution of activity in the various tissues but with reduced amounts suggesting a rapid rate of activity decay.

## Recuction of Activity by Decay

Selected samples of the hay 16 collection from Endiretok were used to determine the rate of activity decay. Counting started on some of this
material on Kay 22 and is being continued with the latest counts having been made on February 19, 1949. The material used in this study of activity decay is listed in Table II. The beta-zanma counts expressed as counts per minute per gram of ret tissue are recorded in Table III With the essential data plotted in Figure 1.

The data show a very rapid decay of the energy from mid-!!ay to mid-September. From September to miderebruary the counts o: all the samples continued to decrease but at a much slower rate. Fitting a straight line to the last three points of the curve ie. for November 27, January 1 and February 19, the half-life period is approximately 180 days.

The slope of the curves at the beginning and at the end tempts one to postulate that the predominant active materials may be $1 a^{2}{ }^{24}$ and $\mathrm{Ca}^{45}$.

WiNERSTY HBCHILES

Sumnary
Marine organisms were collected on May 16, 1948, from the shallow waters of the reef about one and one-fourth miles north of gunit Island for the purpose of determining the beta-gamma radiation.

Samples of about one gram wet weight were reduced to an ash for counting. In the fish samples the skin, muscle, bone, liver, gut, and gills were sampled. The entire organism for most invertebrates was used as a sample. A total of 118 samples were prepared and counted.

The greatest concentration of active material was found in the gut but some distribution of radioactive elements to the tissues had started in the short time (one and one-half days) between the fall-out and time of collection.

Decay studies on selected samples show a very rapid rate of initial change. A straight line fitted to the last three points in the decay curves, i.e. for November 27, 1948, Jamary 1, 1949, and Februcry 19, 1949, give a half life period of approximately 180 days.
